Abstract. Logistic regression model is widely used in many studies to investigate the relationship between a binary response variable $Y$ and a set of potential predictors $X$. The binary response may represent, for example, the occurrence of some outcome of interest ($Y = 1$ if the outcome occurred and $Y = 0$ otherwise). When the dependent variable $Y$ represents a rare event, the logistic regression model shows relevant drawbacks. In order to overcome these drawbacks we propose the Generalized Extreme Value (GEV) regression model. In particularly, we suggest the quantile function of the GEV distribution as link function. Strokes are a serious pathology and a neurological emergency involving the vital prognosis and the functional prognosis. In Senegal, strokes account for more than 30\% of hospitalizations and are responsible for nearly two thirds of mortality. In this work, we use the GVE regression model for binary data to determine the risk factors leading to stroke and to develop a predictive model of life-threatening outcomes in central Senegal.

Key words: generalized extreme value model; logistic regression model; stroke.

AMS 2010 Mathematics Subject Classification Objects : 62P10; 62F03.
Résumé. (Abstract in French) Le modèle de régression logistique est utilisé dans beaucoup de domaine pour étudier la relation entre une variable réponse binaire $Y$ et un ensemble de prédicteurs $X$. La réponse peut représenter, par exemple, l'occurrence d'un certain résultat d'intérêt ($Y = 1$ si le résultat s'est produit et $Y = 0$ sinon). Lorsque la variable dépendante $Y$ représente un événement rare, la régression logistique présente des inconvénients notables. Afin de surmonter ces inconvénients, nous proposons le modèle de régression basé sur la loi généralisée des valeur extrêmes (GVE). En particulier, nous proposons le quantile de la loi généralisée des valeurs extrêmes comme fonction de lien. Les accidents vasculaires cérébraux (AVC) sont une pathologie grave et une urgence neurologique mettant en jeu le pronostic vital. Au Sénégal, les AVC représentent plus de 30% des hospitalisations et sont responsables de près de deux tiers de la mortalité. Dans ce travail, nous utilisons le modèle de régression GVE sur des données binaires pour déterminer les facteurs conduisant à un AVC et de développer un modèle prédictif de l'engagement du pronostic vital au Sénégal-central.

1. Introduction
Stroke is a public health issue, a serious pathology and a neurological emergency involving both vital and functional prognosis Biousse (1994), Bogousslavsky et al. (1993). The term "stroke" suggests an unstoppable event and does not suggest that it is a sudden complication of a chronic vascular disease that has been evolving quietly for many years. This definition allows us to say that, stroke is a frequent and serious pathology that causes many disabilities. (see Bousser and Mas (2000)).

Stroke is a sudden loss of brain function due to an infarction or haemorrhage. There are two pathological entities:

Ischemic strokes, also called cerebral infarction or softening of the brain, are most often the result of a thrombus (a clot that forms in an artery), an embolus (a foreign body, most often a clot, which, carried by the circulation, will obstruct the artery downstream), or a narrowing of the artery caused by atherosclerosis (thickening of the inner lining of the arterial wall). Atherosclerosis is the leading cause of ischemic stroke (50-60% of cases).
Hemorrhagic strokes are caused by an effusion of blood into the brain tissue. Their cause is usually high blood pressure or, much more rarely, vascular malformations (angioma, aneurysm), clotting disorders or complications of anticoagulant treatment Grillo et al. (2006).

Logistic regression is widely used to model binary response data in medical studies (Agresti (2002), Celeux and Nakache (1994) and Menard (2002)). An example of a binary response variable is the infection status (infected vs uninfected) with respect to some disease. A logistic regression model can be used to investigate the relationship between the infection status and various potential predictors Hilbe (2009), Nakache and Confais (2003). If \( Y_i \) denotes the infection status for the \( i \)-th individual in a sample of size \( n \) (\( Y_i = 1 \) if the individual is infected, and \( Y_i = 0 \) otherwise), and \( X_i \) denotes the corresponding (\( p \)-dimensional, say) predictor, the logistic regression model expresses the relationship between \( Y_i \) and \( X_i \) in term of the conditional probability \( \mathbb{P}(Y_i = 1|X_i) \) of infection, as:

\[
\log \left( \frac{\mathbb{P}(Y_i = 1|X_i)}{1 - \mathbb{P}(Y_i = 1|X_i)} \right) = \beta^T X_i,
\]

where \( \beta \in \mathbb{R}^p \) is an unknown parameter to be estimated. An extensive literature has been devoted so far to statistical inference in logistic regression models (see Agresti (2002), Celeux and Nakache (1994), Nakache and Confais (2003) and Collet (2003)). Estimation and testing procedures for this class of models are now well established and are available in standard statistical softwares Hilbe (2009).

When the logistic regression model is employed, it is assumed that the response curve between the covariates and the probability is symmetric. This assumption may not always be true, and it may be severely violated when the number of observations in the two response categories are significantly different from each other. This unbalance is not uncommon when we consider binary rare events data (i.e. binary dependent variables with a very small number of ones) which happens with only a small probability. Applying a nonflexible link function to the data with this special feature may result in link misspecification. Consequences of link misspecification have been studied by a number of authors in the literature (see, for example Czado and Santner (1992) and King and Zeng (2001)). In particular, for independent binary observations, Czado and Santner (1992) show that falsely assuming a logistic link leads to a substantial increase in the bias and mean squared error of the parameter estimates as well as the predicted probabilities, both asymptotically and in finite samples. The logistic regression shows same important drawbacks in rare events studies: the probability of rare event is underestimated and the logit link is a symmetric function, so the response curve approaches zero as the same rate it approaches one.

In this context, focusing on binary rare events data, Calabrese and Osmetti (2013) used GEV regression model, that uses the quantile function of the GEV distribution as link function, for analyzing default probabilities and find that its predictive
performance is better than that of the logistic regression predictive model. They point out that logistic regression could underestimate the probability of default of rare events since the link function is a symmetric function. Wang and Dey (2010) used this model for an application to B2B electronic payments system adoption.

The rest of this paper is organized as follows. In Section 2, we describe the GEV regression model adapted to this setting. In Section 3, we apply the GEV regression model to a real data on stroke patients. A discussion, recommendation and some perspectives are given respectively in Sections 4 and 5.

2. Generalized extreme value regression model

Let \((Y_1, X_1), \ldots, (Y_n, X_n)\) be independent and identically distributed copies of the random vector \((Y, X)\) defined on the probability space \((\Omega, A, P)\). For every individual \(i = 1, \ldots, n\), \(Y_i\) is a binary response variable indicating say, the infection status with respect to some disease (that is, \(Y_i = 1\) if the \(i\)-th individual is infected, and \(Y_i = 0\) otherwise). Let \(X_i = (1, X_{i2}, \ldots, X_{ip})'\) be random vectors of predictors or covariates.

The proposed link function based on the GEV distribution (see Wang and Dey (2010)) is given by

\[
G(x|\mu, \sigma, \tau) = \begin{cases} 
\exp \left[ - \left\{ 1 + \frac{\tau (x - \mu)}{\sigma} \right\}^{-1/\tau} \right] & \text{if } \tau \neq 0 \\
\exp \left[ - \exp \left\{ \frac{\tau (x - \mu)}{\sigma} \right\} \right] & \text{if } \tau = 0
\end{cases}
\]  

(1)

where \(\mu \in \mathbb{R}\) is the location parameter, \(\sigma \in \mathbb{R}_+\) is the scale parameter, \(\tau \in \mathbb{R}\) is the shape parameter and \(x_+ = \max(x, 0)\). A more detailed discussion on the extreme value distributions can be found in Coles (2001) and Kotz and Nadarajah (2000). Its importance as a link function arises from the fact that the shape parameter \(\tau\) purely controls the tail behavior of the distribution.

For a binary response variable \(Y_i\) and the vector of explanatory variables \(x_i\), let \(\pi(x_i) = P(Y_i = 1|X_i = x_i)\) the conditional probability of infection. Since we consider the class of Generalized Linear Models, we suggest the GEV cumulative distribution function proposed by Calabrese and Osmetti (2013) as the response curve given by

\[
\pi(x_i) = 1 - \exp \left\{ \left[ (1 - \tau (\beta_1 + \beta_2 x_{i2} + \cdots + \beta_p x_{ip})) \right] + \right\}^{-1/\tau} \\
= 1 - \text{GEV}(-\beta x_i; \tau)
\]

(2)

where \(\beta = (\beta_1, \ldots, \beta_p)' \in \mathbb{R}^p\) is an unknown regression parameter measuring the association between potential predictors and the risk of infection (for a susceptible individual) and \(GEV(x; \tau)\) represents the cumulative probability at \(x\) for the GEV distribution with a location parameter \(\mu = 0\), a scale parameter \(\sigma = 1\), an unknown shape parameter \(\tau\). For \(\tau \to 0\), the previous model (2) becomes the response curve of the log-log model. For \(\tau > 0\) and \(\tau < 0\) it becomes the Frechet and Weibull response curve respectively, a particular case of the GEV one.

The link function of the GEV model is given by
that represents a noncanonical link function. Note the parameters $\mu$ and $\sigma$ are set to fixed constants for model identifiability. Wang and Dey (2010) showed that the GEV link model specified in 2 is negatively skewed for $\tau < \log(2) - 1$ and positively skewed for $\tau > \log(2) - 1$. The link function is approximately symmetric at $\tau = \log(2) - 1$.

The likelihood function for the unknown $p$-dimensional parameter $\beta$ from the independent sample $(y_1, x_1), \ldots, (y_n, x_n)$ is as follows:

$$L_n(\beta) = \prod_{i=1}^{n} \left\{ \left[ 1 - \text{GEV}(-\beta' x_i; \tau) \right]^{y_i} \times \left[ \text{GEV}(-\beta' x_i; \tau) \right]^{1-y_i} \right\}.$$  (4)

We define the maximum likelihood estimator $\hat{\beta}_n$ as the solution of the $p$-dimensional score equation

$$\dot{l}_n(\beta) = \frac{\partial l_n(\beta)}{\partial \beta} = 0,$$  (5)

where $l_n(\beta) = \log L_n(\beta)$ is the log-likelihood function.

**Remark 1.** Wang and Dey (2010) favor a Bayesian analysis since Bayesian methods do not depend on the regularity assumptions required by the asymptotic theory of maximum likelihood. In particular, in the unusual situation where $\tau < -0.5$ and the classical theory of maximum likelihood breaks down, Bayesian inference provides a variable alternative. Then, we use in this setting the bgeva function of the statistical software R.

### 3. A study on Stroke data in Senegal

#### 3.1. Data description

In this section, we consider an application on Stroke data in central Senegal. Stroke is a sudden neurological deficit of vascular origin caused by an infarct or haemorrhage in the brain (see Bogousslavsky et al. (1993) and Biousse (1994) for more details). We consider here a database of size $n = 162$. The data was collected in the context of a prospective and analytical study, carried out on a period of **8 months** from **April 5** to **November 30, 2016** at Medical Imagery Service of both **Matlaboul Fawzeini Hospital** in **Touba** and **Elhadj Ibrahima Niass regional hospital** in **Kaolack** located in central Senegal. Patients with

CT confirmation of stroke were included in the study. We will therefore investigate the factors which may explain an unfavourable evolution of their health status.

In Sénégal, stroke is the most frequent neurological disease. Known for their high mortality and morbidity rates, they account for more than 30% of hospital admissions and nearly two-thirds of the loss of human life (see Sene-Diouf et al. and Touré et al.).

3.2. Results

In this study, the dependent variable is the evolution of the health status of stroke patients (vital prognosis). We denote $Y$ the binary variable defined as follows:

$$Y_i = \begin{cases} 
1 & \text{if the vital prognosis evolves favourably} \\
0 & \text{if the vital prognosis evolves unfavourably} 
\end{cases}$$

Our aim is to

1. Identify the factors leading to stroke;
2. Evaluate the scores of new cases and predict the vital prognosis in these new cases.

We ran a generalized extreme value regression analysis of the model defined as follows:

$$\mathbb{P}(Y_i = 1|x) = 1 - GEV(- (\beta_1 + \beta_2 \times \text{Age} + \beta_3 \times \text{Sex} + \beta_4 \times \text{Stroke-typ} + \beta_5 \times \text{Cardiopathy} + \beta_6 \times \text{Diabetes} + \beta_7 \times \text{Hypertension}) + \beta_8 \times \text{Hemiplegia} + \beta_9 \times \text{Disturb-cons} + \beta_{10} \times \text{Motor-def} + \beta_{11} \times \text{SC-commitment} + \beta_{12} \times \text{Ivh} + \beta_{13} \times \text{Delay}; \tau).$$

The adjusted probability of vital prognosis for the $i$-th individual is given by

$$P(Y_i = 1|x) = 1 - GEV(-(4.381 + 0.4026 \times \text{Age} - 0.618 \times \text{Delay} + 0.635 \times \text{Disturb-cons} - 3.599 \times \text{Motor-def} + 0.502 \times \text{SC-commitment} + 1.383 \times \text{Ivh}; \tau).$$

4. Discussion

In this paper, we have considered the problem of estimating the generalized extreme value regression model for binary response data using stroke data in central Senegal.

Age has a significant influence on the vital prognosis of stroke patients. Older patients are more at risk than other patents. Indeed, age favours the degradation of functioning of blood vessels. This imbalance is also highlighted by the synchronicity of cardiovascular risk factors, which increases the vulnerability to stroke (Diagne et al. (2016), Zuber and Mas (1994)).

For clinical signs, the most evocative are disturbances of consciousness and motor deficiency. These are all disturbances of vigilance, awakening and conscious thought and affected mobility of the upper and/or lower limbs. In fact, more patients in our study population with consciousness disturbances or motor deficiency had an unfavorable evolution of their state of health.

The scanner must be performed urgently, at best within the first six hours after the onset of symptoms. We were also interested in the time between the first signs

of stroke and admission to the health facility and the time between admission and CT scan. The first was more significant for unfavorable evolution of the vital prognosis of stroke patients. This explains why this delay increases the vital prognosis because it reduces the possibilities of functional rehabilitation.

This delay would be linked to various factors:

- The relatively high cost of scan for patients who are often elderly and without financial resources;
- Difficulty and lateness in transporting patients to hospital;
- Some patients were first guided to traditional practitioners before being transferred to hospital.

For severity signs, their appearance seriously engages the vital prognosis:

- Severity Cerebral commitment which is a fearsome mechanical complication of intracranial hypertension leading to the expulsion of some parts of the brain through the intracranial orifices.
- Intraventricular hemorrhages, which are bleeds that enter the ventricles of the brain.

5. Recommendations and Perspectives

Considering the diversity of risk factors and the high cost of medical care, awareness must be raised to enable assistance to be provided at the first signs of a stroke and, above all, to collect more data that would enable the development of guidance and decision-making tools.

In regression model for binary data, it is usually of interest to estimate the probability of infection \( \pi(x) = P(Y = 1|X = x) \), for some given value \( x \) of the covariates and to investigate its properties. Another issue of interest deals with the inference in the generalized extreme value regression model in a high-dimensional setting, when the predictor dimension is much larger than the sample size (this problem arises, for example, in genetic studies where high-dimensional data are generated using microarray technologies).
